Abstract

Considerable prior analysis has gone into the study of zoning restrictions on locational choice and on fiscal burdens, but none addresses the level and distribution of public goods provided under fiscal zoning. Our analysis emphasizes the interplay between land use restrictions and public good provision, focusing on schooling outcomes. We extend existing general equilibrium models of location and the provision of education so that fiscal zoning can be put into Tiebout choice. Some households create a fiscal burden, motivating the use of exclusionary land-use controls by local governments. We then analyze the market effects of different land-use controls (minimum lot size zoning, local public finance with a head tax, and growth restrictions through fringe zoning) and demonstrate how household behavior directly affects the equilibrium outcomes and the provision of the local public good.

JEL Primary Field Name: Public Finance
JEL Classification: H4, H7, I2
Keywords: Tiebout Model, Urban Location Model, Zoning.
1 Introduction

The primary purpose of local political jurisdictions is the provision of public goods tailored to the needs and desires of their resident populations. In his classic paper on the efficiency of local jurisdictions, Tiebout (1956) shows how choice among local areas allows households to sort themselves on the basis of demand for the public good that is provided. But this simple solution breaks down when various realities such as limited numbers of jurisdictions and finance through local property taxes are acknowledged. One important extension of the modeling of residential choice and the provision of various packages of taxes and public goods in the face of these realities has been the introduction of another empirical reality – the existence of various zoning regulations. Zoning constrains the choices of households and alters the equilibrium outcomes, potentially improving the Tiebout equilibrium. By focusing entirely on the locus of taxes and expenditures across jurisdictions, this literature has, however, neglected other important aspects of the residential choices of households. Consideration of these leads to fundamental changes in the equilibrium solutions by households. This paper introduces accessibility as a second basic facet of residential location and then highlights how endogenous zoning affects the equilibrium demands for schools, the primary public good offered by local jurisdictions.

In the world of head taxes and large numbers of jurisdictions, Tiebout sorting leads to an efficient revelation of public good demands and thus supports the optimal provision of the public good. Yet, as has long been recognized, the financing of local jurisdictions through the property tax changes this solution. Some taxpayers, by buying less expensive houses within a jurisdiction, can enjoy
public expenditures that exceed their contribution to revenues, creating a fiscal burden on wealthier households who must make up for this revenue shortfall. If, however, various zoning devices can be employed, it may be possible to exclude the households that create the fiscal burdens.

Considerable prior analysis has focused on the impact of various zoning restrictions on locational choice and on fiscal burdens. In an influential early paper, Hamilton (1975) incorporates endogenous zoning in a model where property taxes finance a local public good, and he shows that zoning allows individuals to separate themselves perfectly by income. Durlauf (1992) considers a dynamic community model in which communities impose a minimum income restriction as a requirement for residence in a community. Henderson (1980) and Epple, Filimon, and Romer (1988) analyze the endogenous choice of zoning regulations in multicommunity models, but they have no public goods. Fernandez and Rogerson (1997) study the effect of zoning regulations on allocations and welfare in a two community model. Recent theoretical work by Calabrese, Epple, and Romano (2007) and Magliocca et al. (2012) provide new theoretical structures and interesting insights. Nonetheless, the prior work on zoning -- particularly fiscal or exclusionary zoning -- has provided both inconclusive theoretical results and quite inconsistent empirical support of the theory (Evans (1999)). The review of the evidence by Quigley and Rosenthal (2005) provides not only a summary of the issues but ideas on how to resolve the conflicting evidence.

Three important things have been missing from this past discussion. First, it is generally assumed that residential choices are solely a function of the fiscal characteristics of a location. This yields perfect sorting across communities in
terms of income and very sharp, and implausible, reactions to changes in the price of local public goods. This conclusion about homogeneous communities, however, conflicts with observations about the nature of U.S. communities. Across the school districts (communities) in the U.S., jurisdictions are quite heterogeneous in terms of income (much more so than in terms of race).\(^1\)

Moreover, the heterogeneity of households should not be taken as evidence that Tiebout sorting is not going on. A number of authors have looked into parts of this heterogeneity of jurisdictions in Tiebout models, as discussed in the comprehensive review of Epple and Nechyba (2004).\(^2\) For example, Edel and Sclar (1974) consider dynamic adjustment to a long run equilibrium. Epple and Sieg (1999) and Sieg et al. (2004) consider how heterogeneous tastes will generate mixtures of incomes within jurisdictions, while Epple, Gordon, and Sieg (2010) introduce location-specific amenities. Nechyba (2000) relies on a fixed and heterogeneous housing stock. None has developed an integrated explanation.

Second, while past work has been motivated by the provision of public goods, little is actually said about the outcomes. The demand by households for schooling outcomes drives not only a portion of local residential choice but also determines the spending for schools and the variation across districts. Both spending variations and the resultant achievement differences have themselves been objects of direct public policy interventions.\(^3\)

Third, a limited number of jurisdictions necessarily implies that some households will not have their ideal provision of public goods met. Additionally, restrictions on households such as the exclusionary zoning considered here will not in general move the locational equilibrium to the full Tiebout optimum.
This paper addresses each of these issues. It imbeds endogenous zoning within a multifaceted model of locational choice that allows for non-fiscal elements of location. Additionally, it focuses on the most important local public good -- schools -- and considers how zoning affects the level and distribution of educational outcomes. In the course of this, we can also consider how different forms of taxation affect the analysis.

In order to understand the interactions among these different influences on choices by households when faced with land use constraints, we need to start with behavior that reflects more than just heterogeneous tastes for public goods. We build upon and extend the general equilibrium model of household location and education spending decisions in Hanushek and Yilmaz (2007, 2013). That model merges the classical urban location models and the Tiebout models of community choice so that the basic urban form is consistent with empirical observations on community heterogeneity. By emphasizing multiple motivations in locational choice and household behavior, this starting point permits new insights into the implications of fiscally-motivated land use controls.

This paper focuses on two key issues of exclusionary land use controls. First, to answer why cities use exclusionary land use controls, we show how some households impose a fiscal burden on the local government, leading to motivations for excluding some households from a community. Based on the general framework, we can then consider the market effects of exclusionary land use controls and their distributional implications for both educational outcomes and welfare. The policies considered in the paper are zoning, local public finance with a head tax, and growth restrictions through fringe zoning that limits city expansion.
We present a baseline model of a monocentric city that contains two school districts whose households differ in income and tastes that reflect the value of accessibility, lot size, and public amenities (education) of a location. An absentee landlord holds an auction at each location in which households bid for that location. Each jurisdiction provides education, which is financed through property taxes on residential land. Property taxes are determined by majority voting. Households can move without cost between jurisdictions. In equilibrium, communities are heterogeneous, and some households impose a fiscal burden on the local government.

With this structure, we conduct policy experiments with different types of exclusionary land use and then assess the outcomes in terms of the level and distribution of education. Having a more realistic model of urban structure proves to be especially important in this analysis. Public services are tied to specific locations and communities, but locations also differ in their accessibility and in their housing prices. Ignoring these aspects of location introduces a distortion in the analysis of policy alternatives, leading to very different conclusions from those in simpler models. While exclusive communities can improve their educational quality through land use controls on entry, they impose a cost of increased overall variation in educational quality across the area.

This paper is organized as follows. We first develop the theoretical framework within a basic two-jurisdiction, monocentric city model. Because this model is not amenable to analytical solutions, we then calibrate this model to a prototypical city and present benchmark results. Finally, we introduce local governmental involvement through land use controls and describe the impacts of the
alternative policies on households in each of the jurisdictions.

## 2 A General Model of Residential Location

This analysis builds on the simplest structure that can provide heterogeneous communities that illustrate the fundamental behavioral trade-offs essential to understanding the impacts of land use constraints. The model is a modification of the monocentric city model of locational choice in which all job opportunities are offered by firms located at the Central Business District (CBD). Firms employ skilled and unskilled workers who get paid wages that depend on skill. Wages are exogenously given, and skilled workers (s) receive a higher wage than unskilled workers (u), i.e., \( w_s > w_u \). As in any other monocentric city models, the city is assumed to have a radial transportation system. Additionally, we divide the city evenly into two school districts of the same size, labeled North School District and South School District. Each school district raises local property taxes to finance their public schools. Thus, locations differ by three attributes: Accessibility, the property tax rate, and quality of education.

The more common depiction of a monocentric city that has a circular central city surrounded by a donut shaped suburban ring is problematic for our analysis.\(^4\) This standard circular structure of cities implies that all locations at any given distance from the employment center are served by a common school district, making it difficult to see the separate influences of location and school quality.

Additionally, there are empirical reasons to consider alternative depictions. The circular city is more of an analytical description than a realistic portrayal of American cities. The variety of cities that result from natural boundaries such as
lakes, rivers, and mountains or from historical development patterns makes the stylized "von Thunen pattern" more a simplifying device than an accurate generalization of city structures (see Rose 1989). While it is possible to correct estimation of density gradients for missing quadrants (see Mills (1972) or Rose (1989)), the simple depiction fails in a significant number of metropolitan areas. Our simple city structure here is seen, for example, in Minneapolis and St. Paul, where a river divides two jurisdictions (and two school districts). This structure is not meant as a portrayal of any specific area, however, but instead is employed as the simplest way to illustrate how accessibility and public goods interact in determining the locational equilibrium. The characterization of a two-city metropolitan area also permits highlighting the implications of a limited range of jurisdictional alternatives within a Tiebout model.

Each household has one working member and one child attending to a public school in her school district. On top of heterogeneity in wages, we introduce additional heterogeneity by allowing households to place a different valuation on education: Some value education more, while some value it less. Thus, we have four different types of households in the city – Skilled Low Valuation Households (SL), Skilled High Valuation Households (SH), Unskilled Low Valuation Households (UL), and Unskilled High Valuation Households (UH).

A household $i \in \{SL, SH, UL, UH\}$ with a residence $r$ miles off the CBD in school district $j \in \{n, s\}$ enjoys education of quality $q_j$ provided to her child, lot size $h > 0$ which proxies residential quality, (numeraire) composite commodity $c > 0$, and leisure $l \in [0, 24]$. For the calibration, our time frame is a day, and hence the household’s problem is formulated over a day. Her preference is given by a Cobb-
Douglas utility function $U(\alpha^i, \eta^i; q, h, c, l) = q^i h^i c^i r^i$, where $\alpha^i \in \{\alpha_H, \alpha_L\}$ is the taste parameter for education and $\eta^i \in \{\eta_H, \eta_L\}$ is the taste parameter for lot size for high education valuation ($H$) and low education valuation ($L$) households.

The working member of household $i$ commutes once a day to her workplace at the CBD. The pecuniary and time costs of commuting are $a/2$ dollars and $b/2$ hours per mile, respectively. Then, household $i$ faces the following budget constraint

$$c_j(r) + (1 + \tau_j) R_j^*(r) h_j(r) + w_i l_j(r) = Y_i(r) = 24w_i - (a + bw_i)r$$

where $Y_i(r)$ is the household’s income net of transportation costs, $\tau_j$ is the property tax rate, and $R_j^*(r)$ is the equilibrium rent per unit of land.

In each community, the amount of taxes paid by a household depends directly on the lot size ($h$), so that a household with a small lot pay less in taxes than a household with a large lot even though both households receive the same public goods (education, as defined below). To deal with the fiscal disparities, one school district, say the one in the South, introduces a zoning regulation that sets a minimum lot size (MLS) per household in residential land use, $\bar{h}_m$. The aim of this policy is to eliminate the smallest houses, i.e., the ones imposing the largest fiscal burdens on the other residents. The school district sets the minimum lot size by majority voting. We can define the bid-rent function of household $i$, which shows the household’s willingness to pay given a fixed utility level. With the minimum lot size zoning, the problem that a household in the South must solve is

$$\Psi(r, u_i, q_j, \tau_j) = \max_{h,c,l} \left\{ \frac{Y_i(r) - c - w_i l}{(1+\tau_j)h} \mid U(\alpha^i, \eta^i; q, h, c, l) = u_i \right\} \text{ subject to } h \geq \bar{h}_m$$

Then, the bid-rent and bid-max lot size function under MLS regulation is given by
\[ \psi_i^j(r) = \begin{cases} \frac{k_i^{1/n_i}}{(1+\tau_i)w_t^{1/n_i}} q_f^{\alpha_i/n_i} Y_i(r)^{\beta_i} Y_i(r)^{-1/n_i} & \text{if } r \geq r_m \\
\frac{1}{(1+\tau_i)^{\bar{h}_m}} \frac{u_i^{\beta_i} Y_i(r)^{\beta_i}(\frac{\tau_i}{w_t^{1/n_i}})^{\frac{1}{\beta_i} + 1}}{(1+\tau_i)^{\bar{h}_m}} & \text{if } r < r_m \end{cases} \] (3)

and

\[ h_j^i(r) = \begin{cases} \frac{\eta_i}{(\eta_i + \gamma_i + \delta_i)^{(1+\tau_i)\psi_i^j(r)}} & \text{if } r \geq r_m \\
\frac{1}{\bar{h}_m} & \text{if } r < r_m \end{cases} \] (4)

where \( k_i = \frac{\eta_i^{\gamma_i + \delta_i}}{(\eta_i + \gamma_i + \delta_i)^{(1+\tau_i)}} \) is a constant, \( r_m \) is the effective constraint distance that is determined by the intersection between the lot size curve, \( h(\cdot) \) and the horizontal line, \( \bar{h}_m \).

(Household \( i \) in the North solves the same problem with \( \bar{h}_m = 0 \). Since the lot size curve is increasing in distance, the household is constrained such that \( h = \bar{h}_m \) whenever \( r < r_m \), and the bid-rent function for household \( i \) becomes a linear and decreasing function in \( r \). Otherwise, it is a nonlinear decreasing function. With this minimum lot size, there are some households in the South that would like to locate on a smaller lot closer to work but cannot.

The land use pattern that arises in equilibrium is determined by the relative steepness of bid-rent functions of the four different household types. Analytically it is not possible to find the spatial order, and we rely on numerical methods to find it. In general, a steeper equilibrium bid-rent curve corresponds to an equilibrium location closer to the CBD. It is worth pointing out that since each household type has a two piece bid-rent function, each with a different slope, household \( i_1 \) can have a steeper bid-rent than household \( i_2 \) on one piece while the steepness order is reversed on the other piece.

We assume a competitive land market (Alonso (1964)) in which households bid for land and absentee land owners offer land to the highest bidder. A landlord may
rent her land to any of four different types of households or leave it for agriculture. When the latter occurs, she gets a fixed bid of $r_d$. Formally,

$$R^*_j(r) = \max_{i \in \{SL, SH, UL, UH\}} \Psi_j(r)$$  \hspace{1cm} (5)

$$t^*_j(r) = \arg\max_{i \in \{SL, SH, UL, UH\}} \Psi_j(r)$$  \hspace{1cm} (6)

where $t^*_j(r), j \in \{n, s\}$, is a function showing the equilibrium occupant of a location at distance $r$ in school district $j$. We assume that our city is closed, and thus the population of each household type is exogenously given. Formally,

$$\int_{t^*_j(r)=i} \frac{\pi r}{s_i(r)} \, dr + \int_{t^*_j(r)=i} \frac{\pi r}{s_j(r)} \, dr = N_i \quad \forall i \in \{SL, SH, UL, UH\}$$  \hspace{1cm} (7)

The population constraints implicitly assume that the land market clears in school district $j \in \{n, s\}$. Each school district raises property taxes to finance its public school. Assuming local governments run a balanced budget, we have

$$e_j = t_j \frac{\int_{R^*_j(r)>r_d} R^*_j(r) \, dr}{N_j}$$  \hspace{1cm} (8)

where $N_j$ is the population, and $e_j$ is the expenditure per pupil on schools in district $j$. Note that the integration is done over residential property and hence agricultural land is not part of the tax base.

Characterizing the quality of education has proved difficult. Here, to maintain comparability with the prior literature, we emphasize only educational spending, which can be interpreted as either actual quality of the schools or simply perceived quality. Prior literature has shown that it is difficult to characterize school quality when the outcome is measured by student performance. At the same time, households clearly use spending as a proxy for school quality and factor that into their locational decisions. Thus, we take a positivist view of school quality as it affects consumer behavior. In prior work, we have also
considered the role of peer groups in the production function for schools
(Hanushek and Yilmaz 2007, 2013). However, that formulation unduly complicates
the analysis here without yielding additional insights. Under most formulations, it
will reinforce the basic fiscal forces involved, and we wish to show the operation of
these forces in the simplest fiscal model.

The perceived quality of education in community \( j \) is given by a production
function

\[
q_j = c_1 e_j^{c_2}
\]  

(9)

where \( c_1, c_2 > 0 \) and \( c_2 < 1 \) are constants. Notice that the production function is concave,
implying diminishing marginal returns to expenditure per pupil. The property taxes are
determined by majority voting in each school district. Then, household \( i \) at distance \( r \) in
school district \( j \)’s preferred tax rate is given by the following problem

\[
\max_{\tau_j} \frac{k_t}{R^*_j(r) \eta_i (1 + \tau_j)^{\eta_i} w_i} q_j^{a_i} Y_i (r)^{\eta_i + \gamma + \delta} \quad \text{subject} \quad q_j = c_1 e_j^{c_2} \quad \text{(10)}
\]

subject to

\[
e_j = \tau_j \frac{\int_{R^*_j(r) > r_a} R^*_j(r) \pi r \, dr}{N_j}
\]

The preferred tax rate for household \( i \) is, then, \( \bar{\tau}_i = \frac{c_2 a_i}{\eta_i - c_2 a_i} \). Note that the preferred
tax rate is independent of income and is a function of the household’s valuation of
education.

Events unfold in the following order: At the beginning of each period, myopic
households make their residential choice decisions with the expectation that the last
period’s education and property tax packages would prevail in the current period. Once
they move in, they are stuck. They vote for the next period property tax rate in their
school district. As a result, the quality of education in their school district is determined.
At the beginning of the next period, events start over again.

**Definition:** An equilibrium is a set of utility levels $u_i^*$, $i \in \{SL, SH, U L, U H\}$, market rent curves $R_j^*$ ($r$) $j \in \{n, s\}$, quality of education and property tax rate pairs $(q_j, \tau_j)$, $j \in \{n, s\}$, and equilibrium household type functions $t^*_j(r)$, $j \in \{n, s\}$ such that

- Utility maximizing households choose a location (i.e., a school district and commuting distance) along with lot size, leisure and composite commodity.
- Households and farmers bid for land at each location. The absentee landlord offers her land to the highest bidder.
- Regardless of their location or school district, households of the same type attain the same utility level.
- Education is produced through a production function based on expenditure and is financed through local property taxes on residential land. The property tax in each school district is determined by majority voting.
- Labor and land markets clear.
- The local government budget balances in each school district.

**3 Calibration of the Urban Economy**

Our model is calibrated to match some key stylized facts of a typical skilled high valuation (SH) household and a typical U.S. middle size city. In order to provide a base case for consideration of land use restrictions, we begin with no zoning restriction ($h_m = 0$) in either district.

<< TABLE 1 ABOUT HERE >>

The hourly wages for unskilled and skilled workers are calibrated as $w_{ul} \approx 10$ and
\( w_S \approx 18 \), respectively. These number are obtained from the fact that in the U.S., average weekly hours of persons working full time is about 40 hours and the average annual earnings of high school and college graduate workers in 1997 are $22,154 and $38,112, respectively.\(^{10}\)

Then, the share of leisure in the household’s budget is

\[
\frac{\delta}{\eta_H + \gamma + \delta} = 1 - \frac{40w_S}{24 \times 7 \times w_S} \approx 0.76.
\]

The data on average annual expenditures of some selected MSAs suggest that a household spends about one-fifth of its income on shelter. Therefore, the budget share of composite commodity and land are set to be

\[
\frac{\gamma}{\eta_H + \gamma + \delta} = (1 - 0.76) \times 0.8 \approx 0.19
\]

and

\[
\frac{\eta_H}{\eta_H + \gamma + \delta} = (1 - 0.76) \times 0.2 \approx 0.048,
\]

respectively. Moreover, recall that the preferred tax rate for household \( i \) is given by

\[
\tilde{\tau}_i = \frac{c_2 \alpha_i}{\eta_i - c_2 \alpha_i}.
\]

Clearly, we have two possible preferred tax rates, one for high valuation and another for low valuation households. The one for high (low) valuation type is set to be about 2.2 percent (1.5 percent).\(^{11}\) These values are sufficient to permit calibration of \( \alpha_H, \alpha_L, \eta_H, \eta_L, \gamma, \delta \).

Based on the cost of owning and operating an automobile, the pecuniary cost per mile was 53.08 cents in 1997. Assuming a commuting speed of 15 miles per hour within the city, the pecuniary and time costs of commuting per round trip mile are set to be \( a = $1 \) and \( b = 0.13 \), respectively. In equilibrium, the endogenous urban fringe distance is targeted at about 12 miles in both school districts. The population of the city is set to be 1,500,000 households, which implies approximately a population density of 3,132 households per square mile.\(^{12}\) Approximately, 40 percent of the total population is assumed to be skilled worker households. Moreover, 25 percent of skilled households are assumed to be low valuation households. As for the unskilled households, 75 percent are low

---

\(^{10}\) These values are sufficient to permit calibration of \( \alpha_H, \alpha_L, \eta_H, \eta_L, \gamma, \delta \).

\(^{11}\) Approximately, 40 percent of the total population is assumed to be skilled worker households. Moreover, 25 percent of skilled households are assumed to be low valuation households. As for the unskilled households, 75 percent are low...
valuation households.

The agricultural rent bid $r_a$ is set to be $6,844 per acre per year. The parameters of the education production function are set to be $c_1 = 1.6$, $c_2 = 1.12$ so that property tax rate and quality of education packages are consistent with property tax rate and quality of education packages in school districts that generate the desired population distribution across the city.

4 Unconstrained Locational Decisions

Due to the presence of a radial transportation system, households of each type form a concentric ring, or zone, within each of the two school districts around the CBD, and zones for all household types are ranked by the distance from the city center in the order of steepness of their bid-rent functions in equilibrium. The benchmark equilibrium without land use constraints in our simple model has one school district catering to generally higher income households that have a high valuation on education and the other meeting the demands of lower income families. Nonetheless, given the trade-offs between access and the taxes-public good bundle, both communities have a mixture of all household types.

The results for the benchmark equilibrium are shown in Table 2 and Figures 1 through 3. Our results are quite consistent with the residential pattern observed in the United States. In both cities, households with higher incomes typically locate farther from the CBD, occupying larger dwellings than households with lower income households. Moreover, for each income group, those with high valuation of education live closer to the CBD than those with low valuation of education. This outcome is natural, since those with low valuation of education implicitly value lot
size high – and thus want to live farther out where land is cheaper.

These patterns are shown for the two districts in Figures 1 and 2. (Note that the labeling of the two cities is arbitrary in this benchmark without land use constraints). The price of land varies across locations with distance due to commuting costs, as in a standard urban location model. The North School District follows the same general pattern, although the rents at any given distance from the CBD will be lower because of the lower school quality (discussed below). Across school districts the quality of education and property taxes differ, and in equilibrium each type of household is indifferent to living in either school district. This difference in rents across school districts is simply the capitalization of accessibility and differing quality of education.

The school districts are heterogeneous in both income and tastes, and all types are present in both school districts (Table 2). The table gives the distribution of households by school district as a percent of the total population in the metropolitan area. This heterogeneity of school districts is the result of the two components of a location: access to employment and school quality. All households of a given type in terms of income and tastes for education are happy with their residential location in equilibrium, but some of each type will end up purchasing more access and less schooling in trading off the two at equilibrium prices. This aspect of the model introduces a realism that is important in judging policy alternatives that differentially affect the two school districts.

In our baseline model, Table 2 shows that the South School District provides the best education and is the school district of choice for a disproportionate share of high
valuation households, whether of high or low income (skill) level. This better education does come with a higher price tag, namely higher property taxes than the North School District, but this is the majority vote equilibrium of the households.

<< FIGURE 3 ABOUT HERE >>

Following Hamilton (1975), we have concentrated on property taxes to fund our local education, as consistent with U.S. school finance. Figure 3, the derived tax bill for different households in two school districts, vividly shows the issue of fiscal burden. The use of a property tax implies a low tax liability for households in small houses (small lots), but a high tax liability for households in big houses. As shown in Figure 3, the annual spending of about $2,700 in the South School District is met with an annual tax liability of a small house of about $2,000 but a corresponding liability of $3,600 for each household in a big house. The households with the larger houses are effectively subsidizing the education of those with smaller houses. This observation identifies powerful incentives for school districts to regulate the development of new land.

The fiscal disparities by households imply that there are large incentives in the South district to exclude low income households with their lower consumption of quality housing. Also, the exclusionary incentives in the South are greater than in the North, where school quality and fiscal burdens are less. The fiscal disparity exists in the North but is less with poor households paying about $1,650 in taxes to support a school expenditure of about $2,100. A majority of the residents in the North are low income households. Further, they attract a disproportionate share of high skilled households who have a low valuation of schooling. The predominance
of low income and low valuation households in the North implies that the majority
does not want to raise school spending in the North School District and would not
want to exclude low income residents.

For the rest of the paper, we will study the impact of some alternative land use
policies on the efficient provision of education and how successful they are in
terms of excluding households that would impose a fiscal burden on the
government. In all cases, we consider the case where the South imposes controls,
while the North does not.

5 Land-use Controls

We use this expanded locational choice model to analyze how a local
government can exclude households by some land use controls. We consider
alternative kinds of restrictions (which may or may not be permissible for use by
any given school district, depending on state laws): zoning, lump sum taxation,
and growth restrictions through fringe zoning. Each land use control is designed
by the South in an attempt to exclude those imposing a fiscal burden on the high
income residents. The key questions relate to the effectiveness of each kind of
control and the implications for household location and school quality.

5.1 Minimum Lot Size Zoning

At the benchmark equilibrium, the South school district determines the
minimum lot size (MLS) per household in residential land use, $h_m$, by majority
voting. We assume each household votes for his optimal unconstrained house size
as a minimum lot size. If a larger lot size were chosen, she would be constrained
in housing consumption and would end up with a lower utility level. On the other
hand, a lower minimum lot size (than her optimum) would decrease property tax revenues, would introduce households that bring a fiscal burden, and would lead to a lower quality of schools. As a result of the voting outcome, the South School District requires poor households in small houses to consume at least $h_m = 4428$ square feet.

<< TABLE 3 ABOUT HERE >>

<< FIGURES 4 THROUGH 6 ABOUT HERE >>

In equilibrium, the South school district continues to provide a better education, but there are significant locational changes compared to the benchmark case. A summary of the new equilibrium outcome is found in Table 3 and Figures 4 through 6. All Skilled Low Valuation and nearly one-third of Unskilled High Valuation households from the South school district now find that it no longer best serves their demands. Most of the Skilled High Valuation households now reside in the South, which has become an exclusive city with fewer residents and higher average income. Many of the Unskilled Low Valuation households previously in the South stay in the South, but most of them as well as all Unskilled High Valuation households and a small portion of Skilled High households are now forced to consume an amount of land, $h_m$ that is greater than the bid-max lot size without such a regulation. Thus, some fiscal burden of low income households remains in the South, but it is considerably reduced by the exclusionary zoning.

The spatial location pattern seems at first glance to be puzzling, but it is readily explained. As a result of lower rents and increased accessibility in the North, all Skilled Low Valuation households move to the North. As a result of
higher rents and a high minimum lot size requirement, both Unskilled High and Unskilled Low Valuation households were outbid by Skilled High Valuation households at locations closer to the CBD. Recall that the bid-rent function for a household has two pieces; one piece where she is unconstrained and consumes a lot size bigger than minimum lot size and another piece where she is constrained and consumes the minimum lot size. At locations closer to the CBD, we see the constrained portion of a Skilled High Valuation household’s bid rent curve. Aside from the presence of Skilled High Valuation households around the CBD, the rest of the spatial order is not surprising.

To explain the increasing amounts of annual tax liability of Skilled High Valuation households at locations closer to the CBD in Figure 6, recall that they consume the minimum lot size and their tax liability increases towards the CBD due to increasing land prices. This result is different from Hamilton (1975). In a given school district, both land consumption and tax liability differ across household types, while Hamilton finds that every household in a given school district consumes the same amount of housing in equilibrium and pays the same amount of property taxes.

By extension, it is clearly possible to form a pure Skilled High Households school district in the South by sufficiently raising the Minimum Lot Size (MLS) requirement level. This would make it unattractive for the Unskilled Low Valuation households, who would then prefer the North.

### 5.2 Head Taxes

The commonly-analyzed simple Tiebout model finances the local public goods
with a constant tax for all individuals in a school district. Given the homogeneous nature of each district in the standard Tiebout model, the constant, or head, tax does not have much impact. In our model, however, the heterogeneity of districts in terms of income and equilibrium land consumption implies that the property tax and head tax will operate quite differently.

As should be clear, a head tax would eliminate the fiscal burden.\textsuperscript{15} We consider the possibility of applying a flat tax in the South school district, which is concerned with the presence of the households that impose fiscal burdens on the local government under the property tax. We analyze the implications of setting the head tax in the South at the expenditure per pupil in the benchmark.

\textit{As a result of the new policy, no unskilled workers wish to reside in the South (see Table 4). A few additional skilled low valuation households move the South, compared to the baseline, because of the increased accessibility from the South. But, with the fall in average property values in the North, the quality of schools declines in the North, again compared to the baseline. In total, fewer people now find the South to be an attractive residential location compared to the baseline, and its population is less.}

\section*{5.3 Growth Restrictions}

\textit{An alternative land use policy frequently pursued is simply to deny new development within a city, thus making it more exclusive. For our modeling, we consider (urban) fringe restricted within a certain radius, $r_f$, from the city center}
as a means of constraining growth. Here, $r_f$, is chosen to be ten miles. In order to reduce the fiscal burden of the baseline this policy would have to drive out unskilled households. This would happen if the land that is available for residential allocation in the South is smaller, allocated to the highest bidder, and skilled households can afford to bid more. In the new equilibrium, however, it is not so clear. As shown in Table 5, the quality of education falls in the South compared to the baseline. All Skilled Low Valuation households move to the North School District, fewer High Valuation households reside in the South, and more Unskilled Low valuation households live in the South School District. This policy is not effective at excluding households that impose a fiscal burden on the local government. Once again, skilled households subsidize unskilled households, and the problem of fiscal burden in the South remains.

To understand the failure of such fringe zoning, recall that the spatial allocation of households is determined by the relative steepness of bid-rent curves. In the model, poor households have a steeper bid-rent curve, and they reside in locations closer to the CBD, leading to the failure of this policy to exclude the "right" households.

5.4 Implications for School Quality

The land use control policies all were motivated by reducing the fiscal transfers within a subset of the jurisdictions. A particularly interesting aspect of these policies is their implications for the level and distribution of schooling. Specifically, by ending up with a different distribution of households, some of whom are constrained by the land use policies, the political support for schools
changes in the two districts. Within each district, the combination of majority voting on tax rates and the heterogeneity of households within the districts means that a number of households typically are trading off school quality for accessibility and housing prices – and the educational outcomes will depend on the mix of households in the different communities.

<< TABLE 6 ABOUT HERE >>

We first look at the results for school quality by school district, as summarized in Table 6 and Table 7. In general, the jurisdiction imposing land use controls can maintain as high or higher school quality for those households remaining in the district. However, the quality in the other school district (North) tends to decline. The resulting average quality of schools may or may not decline, but uniformly the spread in quality across districts consistently increases.

With minimum lot size zoning, the gains in school quality in the South district are sufficient to offset the declines in the North so that average school quality increases. With the other policies, however, the average quality declines, implying that these land use controls work against the typical public policy objectives of increasing quality and reducing variance.

<< TABLE 7 ABOUT HERE >>

Simply looking at the results by city, however, is incomplete, because the equilibrium outcomes of the different policies imply considerable movement across cities. An alternative summary is to investigate the school quality outcomes for the different families in our analysis, denominated by either income or valuation of schooling. Table 7 summarizes how the different types make out in equilibrium after the South district imposes the alternative land use controls.
The skilled households and the households that highly value schooling do better in terms of school quality with MLS zoning (compared to the benchmark case), and the skilled workers also improve school quality with the head tax. The growth restrictions through reduced fringe zoning lower school quality for both groups. The unskilled and the low valuation residents, who are generally simply reacting to the policies of the South, find that their school quality generally decreases – although any change is minimal with the reduced fringe zoning.

6 Conclusions

The provision of educational services in the United States is closely tied to residential location. A range of active governmental policies have been aimed at altering both the level and the distribution of education across school districts, and it is clear that these policy deliberations must consider household reactions to policies and the alternative reasons why household choose a given location.\footnote{This analysis focuses on the actions of individual communities to restrict the options available to households through exclusionary zoning and thus to improve their local fiscal situation. We embed our endogenous zoning choices within a simple model that recognizes that a given location offers both accessibility to employment and local schools. The quality of schools depends, however, on the preferences of local voters, something that could change in the aggregate with different policies.} Putting these basic elements together, we can provide a general equilibrium solution to the household location problem that is useful for policy simulations.

We consider schools that are funded by property taxes. But, with heterogeneous communities, the presence of households purchasing different quality of homes can
impose a fiscal burden on the local government, because a household in a small house pays a relatively small amount in taxes compared to school spending. Concerned with the fiscal burden of some households, a local government may try to exclude those households paying less tax than their cost of schooling by means of some exclusionary land use controls: minimum lot size zoning, lump sum tax, or fringe distance (growth limitation) zoning.

We presume that the district with the highest income, the best school quality, and the largest fiscal discrepancies imposes a given land use control, while the other district does not. The resulting population distributions under the alternative policies differ substantially from the open market benchmark case. In terms of the quality of education provided, minimum lot size zoning within our parametrization actually increases average quality of education. However, as the mean quality of education increases, so does inequality, measured by the discrepancy in quality across the jurisdictions. The other cases of permitting head taxes or of reduced fringe zoning (growth controls) tend to lower average school quality while also increasing the variance in quality across districts. It is generally true, however, that the upper income residents, who drive the restrictive zoning, can come out ahead in terms of school quality.

Our theoretical characterization of the equilibrium outcomes is of course dependent upon the specific utility functions and calibration of the model. Alternative calibrations can lead to different results. The important message from our calibrations is, however, that the simplest models of locational choice – ones dependent on just the provision of differing amounts of the local public good – are likely to misstate the locational outcomes and the nature of public good provision.
Specifically, models that lead to perfect sorting of households across communities, à la Tiebout (1956), are likely to misrepresent the outcomes that will result from local policy changes. Moreover, the general equilibrium nature of housing decisions means that the actions of households in one jurisdiction spill over into other jurisdictions, leading to changes not only in the structure of housing prices but also in the overall provision of public goods. These can be very significant when there are limited numbers of jurisdictions as in our modeling here.
Endnotes:

2 From a different perspective, Ortalo-Magné and Rady (2008) introduce income heterogeneity through housing market price dynamics, where people buy houses at different times (and prices).

3 Hanushek and Lindseth (2009) review and analyze school finance deliberations with an emphasis on court involvement in school finance variations across districts.

4 With a circular city structure, the radial symmetry permits straightforward analytical solutions of location where it is necessary only to trace locational choices along any ray from the employment center. It has also motivated a large number of empirical analysis of urban form that are based on estimating household density functions and price gradients emanating from the center (see, for example, Mills(1972), Rose(1989), and Kim(2007)). See also de Bartolome and Ross (2003) or Cassidy, Epple, and Romer (1989). Note that as demonstrated below our cities have some similar structure in that there is "ring-separation" of different household types within each jurisdiction.

5 Kim(2007) describes a number of situations where the standard depiction does not work including, importantly, the significant numbers of U.S. metropolitan areas with multiple central cities or other anomalies. Bertaud and Malpezzi (2003) also find a number of international cities are inaccurately described by smooth density gradients.
For simplicity, public schools are the only means to provide education in our model. We do not consider private schools. See Hanushek, Sarpcça, and Yilmaz (2011) for a model with private schools.

It is implicitly assumed that each household manages the construction of his house by himself and that lot size indexes the overall quality of the residential services.

The pecuniary cost of commuting is an important parameter in the model, without which we cannot find the spatial order of households by income. Empirically, pecuniary costs are not negligible in U.S. See Altman and Desalvo (1981) for an early estimate. Internet sites offer commuting cost calculators that put the 2011 cost per mile at over $1 (see, for example, http://commutesolutions.org/external/calc.html [accessed December 26, 2011]).

The source of statistical facts we use is the Statistical Abstract of the United States; see U.S. Bureau of the Census (1998).

Based on a real interest rate of 2.5 percent, those values are the effective tax rates based on the value of a house.

The median population per square mile of cities with 200,000 or more population was 3,546 in 1992. Source: County and City Data Book; see U.S. Bureau of the Census (1994).

Note that there is a trivially different equilibrium where South and North are simply switched. In each case, however, our prior work shows that the solution converges on the same equilibrium, independent of the starting point chosen, when there are no peer effects in the educational production function. See Hanushek and Yilmaz (2007).

In 1997, the average expenditure per pupil was $5,923 of which 45 percent comes from local funds. Source: U.S. Department of Education (2004). Our analysis assumes that both
cities get equal per student allocations of state and federal funds for education, and that is not considered in the household decision making.

15 While head taxes are not common in the U.S., they are used partially to finance schools in California. The introduction of a property tax limitation (Proposition 13) effectively set the property tax rate at a constant across the state. Individual districts may, with voter approval, establish a parcel tax that is the same for all residences in the school district regardless of their value.

16 Note that we think of this as maintaining restrictions on any expansions in the city, as is typical of many European cities. A policy to actually move the fringe in clearly reduces the value of property that was formerly residential and the owners would have to be compensated for such actions. Also, if the fringe moves out, so that the population expands, the new equilibrium can imply a reduced school quality for the South district.

17 See, for example, the early study of Feldstein (1975) on state school finance options. More recent analysis incorporates accessibility into the analysis of governmental policy (Hanushek and Yilmaz (2007, 2013)).
